Abstract—BCH (Bose-Chaudhuri-Hocquenghen) error correcting codes ([1]-[2]) are now widely used in communication systems and digital technology. Direct LFSR(linear feedback shifted register)-based encoding of a long BCH code suffers from serial-in and serial-out limitation and large fanout effect of some XOR gates. This makes the LFSR-based encoders of long BCH codes cannot keep up with the data transmission speed in some applications. Several parallel long parallel encoders for long cyclic codes have been proposed in [3]-[8]. The technique for eliminating the large fanout effect by J-unfolding method and some algebraic manipulation was presented in [7] and [8]. In this paper we propose a CRT(Chinese Remainder Theorem)-based parallel architecture for long BCH encoding. Our novel technique can be used to eliminate the fanout bottleneck. The only restriction on the speed of long BCH encoding of our CRT-based architecture is $\log_2 N$, where N is the length of the BCH code.

Index Terms— Systematic BCH encoding, CRT(Chinese Remainder Theorem), fanout, LFSR(linear feedback shifted register), parallel processing

I. Introduction and Preliminaries

BCH codes were introduced in [1-2] and have been extensively studied. Let $GF(2^t)$ be a finite field of 2^t elements and $\alpha \in GF(2^t)^* = GF(2^t) - \{0\}$ be a primitive element. $(c_0, \dots, c_{N-1}) \in GF(2)^N$, where, $N = 2^t - 1$, is a codeword of the BCH code $C(\delta)$ of designed distance δ , if $\sum_{i=0}^{N-1} c_i \alpha^{ij} = 0$ for $j = 1, 2, \dots, \delta - 1$. It is well-known that the minimum Hamming distance of $C(\delta)$ is at least δ . For any polynomial in $GF(2)[x]$, it can be factorized to the product of some irreducible polynomials in $GF(2)[x]$ (see [11]). Let $w_1(x), \dots, w_r(x) \in GF(2)[x]$ be the distinct monic irreducible polynomials whose zeros are of the form $\alpha^{2^d j} \in GF(2^t)$, where d is arbitrary non negative integer. We know that the generator polynomial $g(x)$ is the product $g(x) = w_1(x) \cdots w_r(x)$. It is clear $\deg(w_i(x)) \leq t$ for $i = 1, \dots, r$ (see [10]).

Example 1(see [10]). Let $C \subset GF(2)^{15}$ be the [15, 5, ≥ 7] BCH code with zeros $\alpha^1, \dots, \alpha^6 \in GF(16)$, where α is a primitive element of $GF(16)$. Its generator polynomial $g(x) = x^{10} + x^8 + x^5 + x^4 + x^2 + x + 1 = (x^4 + x + 1)(x^4 + x^3 + x^2 + x + 1)(x^2 + x + 1)$.

For a BCH code of length $2^t - 1$ and dimension $2^t - 1 - \deg(g(x))$, the number r is determined by the cyclotomic coset decomposition of the zero set $\{\alpha^1, \dots, \alpha^{\delta-1}\}$.

Example 1 (continued, see [10]). We have 3 cyclotomic coset $\{\alpha^1, \alpha^2, \alpha^4, \alpha^8, \dots\}$, $\{\alpha^3, \alpha^6, \alpha^{12}, \alpha^9, \dots\}$, $\{\alpha^5, \alpha^{10}, \dots\}$. Thus

we have $r = 3$.

Since 1 is not a zero of the polynomial $g(x)$, it is clear $r < \frac{\deg(g(x))}{2}$. Actually, most of the cyclotomic sets are of the size t , r is roughly $\frac{\deg(g(x))}{t}$. When t is a prime number, we know each cyclotomic coset except $\{1\}$ is of the size t (see [11]). Thus $r = \frac{\deg(g(x))}{t}$ when t is a prime(see Example 2 and 3 below).

The systemic encoding of a cyclic code with generator polynomial $g(x)$ ($\deg(g(x)) = n - k$) and code length n is processed as follows. For a k -bit message $\mathbf{m} = (m_{k-1}, \dots, m_0) \in GF(2)^k$, set $m(x) = m_{k-1}x^{k-1} + \dots + m_1x + m_0 \in GF(2)[x]$, then the encoded codeword is $\mathbf{c} = (c_{n-1}, \dots, c_0) \in GF(2)^n$ such that $c(x) = c_{n-1}x^{n-1} + \dots + c_1x + c_0 = m(x)x^{n-k} + \text{Rem}_{g(x)}(m(x)x^{n-k})$, where $\text{Rem}_{g(x)}(f(x))$ is the remainder polynomial dividing $f(x)$ by $g(x)$, that is, $f(x) = q(x)g(x) + \text{Rem}_{g(x)}(f(x))$, $\deg(\text{Rem}_{g(x)}(f(x))) < \deg(g(x))$.

For multiplying the input polynomial $u(x) \in GF(2)[x]$ by a polynomial $h(x) \in GF(2)[x]$, we have a LFSR circuit to implement the multiplication with at most $nz(h) \leq \deg(h(x)) + 1$ XOR gates, where $nz(h)$ is the number of non zero coefficients in $h(x)$. For dividing the input polynomial $u(x) \in GF(2)[x]$ by the polynomial $h(x) \in GF(2)[x]$, we have a LFSR circuit with at most $nz(h)$ XOR gates, which outputs the remainder polynomial of the division (see [10-11]).

Long BCH codes can sometimes achieve better performance than RS(Reed-Solomon) codes, which is now widely used in digital video broadcasting, optical communication and magnetic recording systems. Hence BCH codes are of great interest. Long BCH encoding and decoding can be implemented directly by linear feedback shifted register(see [3] and [10]). However this LFSR-based architecture suffers from serial-in and serial-out limitation and large fanout effect. The LFSR-based systemic encoding of a long BCH code is actually a *division circuit* with the divisor $g(x)$ (see [10]) and the large fanout of some XOR gate would lead to large gate delay. In high-speed applications such as optical communication systems and digital video broadcasting, such LFSR-based long BCH encoding cannot keep up with the data transmission speed. Thus faster parallel processing of long BCH encoding is needed.

Several parallel encoding architectures for long cyclic codes have been proposed in [4-6]. In [7] and [8], K. K. Parhi et al presented the technique of parallel architecture of long BCH encoding based on J-unfolding method(see [9]), which can eliminate the large fanout effect.

In this paper we give a parallel architecture of long BCH encoding which is based on Chinese Remainder Theorem (CRT, see [11]). The basic idea is the transformation of the

above long division LFSR circuit of the generator polynomial $g(x)$ by several short division LFSR circuits of low degree polynomials $w_1(x), \dots, w_r(x)$ in parallel. In this process, we need some multiplication LFSR circuits which have no large fanout. The advantage of our novel parallel architecture is the only limitation on number of the fanout of the CRT-based long BCH encoding is $\log_2 N$, where N the code length of the BCH code.

II. CRT-based Parallel Architecture of Long BCH Encoding

We need to recall Chinese Remainder Theorem. Let $f(x), g(x) \in GF(2)[x]$ be two polynomials. Suppose $g(x) = g_1(x) \cdots g_r(x)$, where $g_1(x), \dots, g_r(x)$ are pairwise co-prime, that is, $\gcd(g_i(x), g_j(x)) = 1$ for any two distinct i and j . Let $g'_i(x) = \frac{g(x)}{g_i(x)} \in GF(2)[x]$ for $i = 1, \dots, r$. It is clear $\deg(g'_i(x)) = \deg(g(x)) - \deg(g_i(x))$ and $\gcd(g'_i(x), g_i(x)) = 1$. By using generalized Euclid algorithm we can find a polynomial $g''_i(x)$ such that $\deg(g''_i(x)) < \deg(g_i(x))$ and $g''_i(x)g'_i(x) \equiv 1 \pmod{g_i(x)}$ (i.e. $g''_i(x)g'_i(x) - 1$ can be divided by $g_i(x)$). We have the following result.

$$\text{CRT (see [11]).} \quad \text{Rem}_{g(x)}(f(x)) = \sum_{i=1}^r g'_i(x) \text{Rem}_{g_i(x)}(g''_i(x)f(x)).$$

Let $g(x) = w_1(x) \cdots w_r(x)$ be the generator polynomial of a BCH code, where $w_1(x), \dots, w_r(x)$ are the distinct irreducible polynomials in $GF(2)[x]$ as in the previous section. From the theory of the finite field (see [11]), $\deg(w_i(x)) \leq t$, a fixed constant around $\log_2 N$, where $N = 2^t - 1$ is the code length of the BCH code. It is clear that these polynomials are pairwise co-prime. Set $w'_i(x) = \frac{g(x)}{w_i(x)}$. Let $u_i(x) \in GF(2)[x]$ be the unique polynomial such that $u_i(x)w'_i(x) \equiv 1 \pmod{w_i(x)}$.

From CRT $\text{Rem}_{g(x)}(m(x)x^{n-k}) = \sum_{i=1}^r w'_i(x) \text{Rem}_{w_i(x)}(u_i(x)m(x)x^{n-k})$, we can have a parallel architecture for getting $\text{Rem}_{g(x)}(m(x)x^{n-k})$ immediately. First we have r parallel LFSR circuits multiplying $u_1(x), \dots, u_r(x)$, then r parallel LFSR circuits dividing $w_1(x), \dots, w_r(x)$; r parallel LFSR circuits multiplying $w'_1(x), \dots, w'_r(x)$ in the third step and finally a circuits summing the outputs from the previous circuits.

Here the fanout effect of the LFSR circuits dividing by $w_1(x), \dots, w_r(x)$ is upper bounded by t , which is around $\log N$. It is well known that the multiplying and summing LFSR circuits have no large fanout effect and can be execute with small latency. Comparing with the direct LFSR-based architecture, though the number of clock cycles is perhaps increased in our architecture, the clock period is substantially decreased by eliminating the large fanout effect. Thus our parallel architecture of getting $\text{Rem}_{g(x)}(m(x)x^{n-k})$ (the systemic encoding of the BCH code) is suitable in the high speed applications. The speed of this CRT-based parallel

architecture of long BCH encoding is essentially dependent on the number t , which is around the $\log_2 N$, where N is the code length of the BCH code.

III. Implementation and Further Comments

In this section the implementation and the cost of the CRT-based architecture of long BCH encoding are given.

Implementation:

Step 1. Multiplication LFSR of polynomials $u_1, \dots, u_r$ with the input polynomial $m(x)x^{n-k}$. Here the circuits need $\sum (\deg(u_i) + 1)$ XOR gates.

Step 2. Division LFSR of polynomials $w_1, \dots, w_r$ with the inputs of outputs of the circuits in the Step 1. Here the circuits need $\sum (\deg(w_i) + 1)$ XOR gates.

Step 3. Multiplication LFSR of polynomials $w'_1, \dots, w'_r$ with the inputs of the outputs of the circuits in the Step 2. Here the circuit need $\sum (\deg(g) - \deg(w_i) + 1)$ XOR gates.

Step 4. The summation LFSR of the r outputs in Step 3. Here the circuit need at most $r(t + 1)$ XOR gates.

We can get a upper bound on the number of XOR gates used directly, it is upper bounded by $\sum (\deg(u_i) + 1 + \deg(w_i) + 1 + \deg(w'_i) + 1) + r(t + 1) \leq 2r(t + 1) + r(\deg(g) + 2)$. From the estimation of r , this number is roughly $2\deg(g) + \frac{\deg(g)}{t}(\deg(g) + 2)$.

Example 2 (see [7]). We consider the BCH code with code length $2047 = 2^{11} - 1$ and dimension 1926. Its generator polynomial is a degree 121 polynomial $g(x) \in GF(2)[x]$, which is the product of 11 distinct irreducible polynomials $w_1, \dots, w_{11}$ of degree 11. Thus our architecture need at most 1595 XOR gates. The number of fanout is upper bounded by the $\deg(w_1), \dots, \deg(w_{11})$, which is at most 11. In some sense this is better then the architecture in [7].

Example 3 (see [8]). We consider the BCH code with code length $N = 2^{13} - 1$ and dimension 7684. Its generator polynomial is a degree 507 polynomial $g(x)$ in $GF(2)[x]$. $g(x)$ is the product of 39 degree 13 distinct irreducible polynomials in $GF(2)[x]$. Thus our architecture need at most 20865 XOR gates. The number of fanout XOR gates in the architecture is at most 13. In some aspect this is better than the architecture in [8].

It is clear the idea can be used for systematic encoding for any long cyclic code with generator polynomial $g(x) = g_1(x) \cdots g_r(x)$, where $g_1, \dots, g_r$ are pairwise co-prime polynomials. Secondly in some cases, if we can choose the generator polynomial with the same code parameters, it is better to use the generator polynomial $g(x) \in GF(2)[x]$ with the property that the numbers of nonzero coefficients in $g_1, \dots, g_r$ are as small as possible. However the idea of CRT-

based architecture can not be used for the encoding of long CRC codes (see [4-6]) because the generator polynomials of CRC codes are irreducible.

IV. Conclusion

In this paper we have presented a CRT-based high speed parallel architecture for long BCH encoding. The architecture can be used to eliminate the large fanout effect. The only limitation of this CRT-based parallel architecture is the logarithm of the code length of the BCH code. It should be noted that our architecture of using CRT for transforming the long division LFSR of polynomial $g(x) = g_1(x) \cdots g_r(x)$, where $g_1, \dots, g_r$ are pairwise co-prime, to short division LFSR in parallel can be used for systematic encoding of any long cyclic code generated by $g(x) \in GF(2)[x]$.
